Guidelines on the Management of a Child with Sickle Cell Disease and low Haemoglobin

Aim
This guideline describes the management of children in King’s College Hospital with Sickle Cell Disease who may have symptomatic anaemia. It applies to patients with sickle cell disease who are currently under the care of the Paediatric Haematology team or have been admitted to a paediatric ward. It is mainly written as a tool for the medical team managing these patients, but any member of the multidisciplinary team may find it useful.

This guideline provides advice on the assessment and management of children with sickle cell disease who are found to have low haemoglobin, more than 3g/dl below their steady state or less than 5g/dl. This principally involves two conditions: acute sequestration and transient red cell aplasia due to Parvovirus B19 infection. Severe anaemia may occur as part of an episode of acute pain or acute chest syndrome but will be dealt with in guidelines specifically dealing with these problems.

Background
Steady-state haemoglobin varies widely in children with sickle cell disease, from about 5 - 11g/dl. The results of blood counts need to be interpreted in the light of the known steady state which will typically be available on EPR. If there is no record of steady-state haemoglobin, the parents or child may know the normal level. Haemoglobin less than 5g/dl is likely to be significant. Similarly spleen and liver size need to be compared to the steady-state size, which should be recorded in the notes and in the documents tab on EPR. The spleen is palpable in many children between the ages of 1 and 3 years, and typically becomes progressively smaller after that. Some children have persistent splenomegaly, which can be massive. Similarly, the liver can be chronically enlarged, and its size is difficult to interpret unless the steady state is known.

History and Examination
Severe anaemia should be suspected in children with any of the following symptoms and signs: pain, dyspnoea, tiredness, lethargy, fever, pallor, increased jaundice, splenomegaly, hepatomegaly, tachycardia, tachypnoea. History and examination should elucidate these features in all ‘unwell’ children with sickle cell disease. Severe anaemia can be present in a relatively well child, who does not have pain.

Children may have had finger-prick haemoglobin measured in A&E, and any low readings should be confirmed by formal laboratory testing.

Investigations
If anaemia is thought possible, the following tests should be performed:
- FBC
- reticulocyte count
- group and save
- urea and electrolytes
- liver function tests.

Interpretation of Investigations
Low Hb, reticulocyte>200x10^9/l, spleen larger than in steady state (or palpable if previous spleen size unknown)
- probable splenic sequestration.

Low Hb, reticulocyte>200x10^9/l, liver larger than steady state, no increased splenomegaly
- probable hepatic sequestration (rare).
Low Hb, reticulocyte count <100x10^9/l
- probable red cell aplasia due to Parvovirus B19 infection.

Other results interpreted depending on clinical situation, previous findings.

**Acute Splenic Sequestration**
Typically occurs under 3 years of age, but can occur in older children who have persistent palpable splenomegaly i.e. those with HbSC, HbS/β thalassaemia, HbSS with α thalassaemia. It is often precipitated by infection

**Symptoms:** collapse, shock, fever, abdominal pain, lethargy

**Signs:** Splenomegaly (often increasing rapidly in size over a few hours), pallor, tachycardia, tachypnoea, hypotension.

**Investigations:** as above plus blood cultures.

**Initial Management:**
1. If shocked, resuscitate with intravenous fluids and emergency blood – O RhD negative according to APLS algorithm.
2. If not shocked, await results, cross-matched blood. If the spleen is enlarging or Hb<5g/dl, blood transfusion will usually be necessary, to increase Hb to about 10g/dl.
3. Start intravenous antibiotics – piperacillin with tazobactam (tazocin) (90mg/kg 6 hourly) and gentamicin (7mg/kg once per day, trough level to be checked prior to the third dose.) If the patient has a known allergy to penicillin, ciprofloxacin (intravenous, 4mg/kg 12 hourly) and gentamicin should be given. Antibiotics should be continued until the child is clinically better and may be adjusted depending on the results of blood cultures. Typically the child will be discharged on their normal dose of penicillin prophylaxis, although a course of oral antibiotics may be given, depending on the clinical situation and the results of blood cultures.
4. Monitor and record spleen size 6 hourly.
5. Repeat FBC 12 hourly until stable, or more frequently if clinical deterioration.
6. Treat other complications e.g. pain according to other protocols.
7. Utrasound of the abdomen may be helpful but should not delay resuscitation and transfusion

**Further Management**
Patients should be kept in hospital until pain and other symptoms have resolved, and the spleen size is stable or reducing and the haemoglobin has been stable for 24 hours
Parents should be warned that recurrent episodes can occur and the symptoms explained. They should be shown how to feel the spleen and know to feel it if the child develops symptoms. They should know to bring the child to hospital urgently if symptoms recur or the spleen is thought to be enlarging.
The child should be seen in outpatients in 5 to 7 days. If episodes recur, splenectomy may be appropriate.

**Hepatic Sequestration**
Hepatic sequestration can occur at any age, and is a less well defined than splenic sequestration. In general, acute enlargement of the liver accompanied by falling haemoglobin
constitutes hepatic sequestration, and treatment is similar to that given for splenic sequestration. Rapid enlargement and shock are less common, but deteriorating liver function and very rarely acute liver failure can occur.

**Symptoms:** abdominal pain (right upper quadrant), abdominal distension, lethargy, malaise

**Signs:** Enlarging tender hepatomegaly, increasing jaundice.

**Investigations:** as above with blood cultures, clotting screen. Ultrasound of the abdomen may be helpful but should not delay resuscitation and transfusion.

**Acute Management:**
1. If shocked, resuscitate with intravenous fluids and emergency blood – O RhD negative.
2. If not shocked, await results, cross-matched blood. If the liver is enlarging or Hb<5g/dl, blood transfusion will usually be necessary, to increase Hb to about 10g/dl. If the patient is in severe abdominal pain and clinically deteriorating, an exchange transfusion should be considered.
3. Start intravenous antibiotics – piperacillin with tazobactam (tazocin) (90mg/kg 6 hourly) and gentamicin (7mg/kg once per day,, trough level to be checked prior to the third dose.) If the patient has a known allergy to penicillin, ciprofloxacin (intravenous, 4mg/kg 12 hourly) and gentamicin should be given.
4. Monitor and record liver size 6 hourly.
5. Repeat FBC, LFT’s and INR 12 hourly until stable, or more frequently if clinical deterioration.
6. If liver failure occurs, discuss with on-call liver team.
7. Treat other complications e.g. pain according to protocols.

**Further Management**
If liver remains enlarged or liver function tests markedly deranged, arrange further investigations following discussion with hepatologists.
**Acute Red Cell Aplasia**

The combination of a low haemoglobin with low reticulocyte count is called acute red cell aplasia. This is nearly always caused by Parvovirus B19 infection, although other viruses may cause this to a lesser extent eg Influenza. Parvovirus B19 infection will also cause a reduction in platelet and white cell count, although this is usually not clinically significant. Thrombocytopenia (Platelets <50x10^9/l) or neutropenia (Neutrophils<1 x10^9/l) are not typical and should be further investigated.

**Symptoms:** lethargy, tiredness. Parvovirus may also cause high fevers, abdominal pain, ‘Slapped–cheek syndrome’, Fifth Disease, arthritis, nephritic syndrome.

**Signs:** Pallor, lymphadenopathy, tachycardia, tachypnoea, fever (jaundice is usually absent)

**Investigations:** FBC, reticulocyte count, Parvovirus B19 serology, Group and Save/Cross match, Urea and electrolytes, liver function tests. Urine albumin:creatinine ratio.

**Acute Management:**
1. If shocked, resuscitate with intravenous fluids and emergency blood – O RhD negative according to APLS algorithm.
2. If not shocked, await results, cross-matched blood and transfuse to a haemoglobin of 8-10g/dl.
3. Start intravenous antibiotics if febrile, usually cefuroxime (20mg/kg 8 hourly, maximum 750mg 8 hourly).
4. Repeat FBC, reticulocytes daily.
5. Treat complications e.g. pain according to other protocols.
6. If Parvovirus infection is thought likely (anaemia and reticulocytopenia), the patient should be reverse-barrier nursed in a side-room. Particular care should be taken to keep the patient isolated from patients who might be immunosuppressed. The patient should not receive nursing or medical care from staff who are, or might be, pregnant.
7. The family should be warned that other family members/contacts with haemolytic anaemias might also develop significant anaemia, and blood tests arranged if appropriate.

**Further Management**

Once the haemoglobin has been corrected by transfusion and the patient is stable, the patient can be discharged before the reticulocyte count has recovered. A follow-up appointment should be made for 3-5 days later to document blood count recovery.
